The range of clinical presentations of HIV-related disease in Africa has not been adequately described, despite the fact that many hospitals have to rely heavily on clinical diagnosis. Six hundred adult medical patients seen in the Casualty Department of the main Government hospital in Nairobi were enrolled in a study of the presentation and outcome of HIV-related disease: 506 of these patients were admitted, of whom 19 per cent (95) were HIV seropositive. The remaining 94 were dealt with as outpatients: 11 percent (10) of these were seropositive. A history of prior treatment for sexually transmitted disease and, if male, being uncircumcised, were associated with being seropositive. Three presentations were strongly associated with HIV infection: acute fever with no focus except the gastrointestinal tract (enteric fever-like illness), acute cough with fever (community-acquired pneumonia) and chronic diarrhoea with wasting. The WHO clinical case definition (CCD) for AIDS missed a substantial amount of HIV-related morbidity (sensitivity 39 per cent) and misidentified many
seronegative patients (positive predictive value 59 per cent). In comparison with
the Centers for Disease Control surveillance definition for AIDS, the CCD was
specific (91 per cent) and sensitive (79 per cent) but only had a positive
predictive values of 30 per cent: the CCD may therefore be a poor surveillance
tool for AIDS. Seropositive patients were much more likely to die than were
seronegative patients (39 per cent vs. 15 per cent mortality). Enteric fever-like
illness was the presentation which most commonly proved fatal. A wider spectrum
of disease is associated with underlying HIV immunosuppression than has
previously been described in Africa.
